13 **Abstract**

14 Land preparation for planting sugarcane (*Saccharum* inter-specific hybrid) generally
15 consists of multiple tillage passes to remove the old stool and the compacted inter-rows.

16 The next crop is usually planted in the old inter-row area to minimise the effect of

17 *Pachymetra chaunorhiza*, a soil borne disease which builds-up under the old crop row.

18 However, in order to adopt reduced tillage and not be adversely affected by soil

19 compaction in the old inter-row it is necessary to re-plant into the old crop row. The

20 hypothesis tested was: would reduced tillage and planting back in the old crop row in

21 conjunction with rotation of resistant and susceptible cultivars minimise the effect of this

22 soil borne disease on crop yield ? Field experiments were undertaken on Alfisol soils,

23 near Tully in north Queensland and Bundaberg, south Queensland, Australia to compare

1 reduced tillage with conventional cultivation for planting sugarcane on soil known to
2 have the soil borne disease *Pachymetra chaunorhiza*. Conventional cultivation involved
3 intensive land preparation with a 6-10 month bare fallow and this was compared with
4 three different types of reduced tillage. With the reduced tillage treatments only the old
5 row area was treated not the inter-row. The reduced tillage treatments included (1)
6 mechanical stool removal with a 6-10 month bare fallow, (2) chemical spraying to kill the
7 stool with a 6–10 month fallow period followed by cultivating the row area prior to
8 planting and (3) mechanical stool removal and replanting with no fallow period. The
9 crop was planted directly back into the previous crop row in the reduced tillage
10 treatments and as close as possible in the conventional treatment by planting from the
11 same edge of the field as the original crop and using the same row spacing. Two cultivars
12 were grown at each site, one resistant and one susceptible to the known fungal root
13 pathogen *Pachymetra chaunorhiza*.

14 Results showed that, providing *Pachymetra* resistant cultivars were used, there was no
15 yield reduction with reduced tillage and in most situations reduced tillage enhanced cane
16 and sugar yields. Further, with the *Pachymetra* resistant cultivar there was no adverse
17 effect from planting directly into the old cane row from the previous cycle. Levels of
18 *Pachymetra* remained low under the resistant cultivar but increased under the susceptible
19 cultivar as the crop cycle progressed. When a resistant cultivar was planted after a
20 susceptible cultivar yields were not compromised while a susceptible cultivar following a
21 resistant cultivar did not produce a significantly lower yield in the following plant crop
22 but there were indications that yields would be reduced later in the crop cycle. Over a
23 crop cycle of a plant and three ratoon crops in the Bundaberg experiment the average

1 yields of the susceptible and resistant cultivars were 114 and 89 t/ha, respectively, an
2 increase of 28% with the resistant cultivar.

3
4 Earthworm numbers recovered more rapidly after reduced tillage compared with
5 maximum soil disturbance at planting suggesting that in the medium to long-term soil
6 health will benefit by the adoption of reduced tillage for planting sugarcane. Reduced
7 tillage did not enhance the population of pathogenic nematodes.

8
9 It is concluded that cultivars are available to allow the adoption of reduced tillage in
10 Pachymetra susceptible areas without compromising crop yield. Reduced tillage will
11 result in substantial cost savings.

14

15 **1. Introduction**

16 In times of low commodity prices and economic downturn, growers look for ways to
17 reduce the cost of production. When the time comes to plant a crop, reduced tillage is a
18 means by which the cost of land preparation for planting can be reduced. (Braunack et al.,
19 1999; McGarry et al., 2001). Previous studies on reduced tillage for sugarcane planting
20 were undertaken to reduce erosion on sloping land (Holmes and Verri, 1988), conserve
21 soil moisture and reduce costs through minimising the number of tillage operations
22 (Trowse, 1982). In most instances the crop was replanted as near as possible to the old
23 inter-row (McIntyre and Barbie, 1989) and on occasion back into the old row (Burgess,

1 1986) with little consideration of the impact of row location on soil-borne pests and
2 insects.

3

4 However, many growers have expressed concern that planting back into the old row is
5 likely to result in a build-up of the soil-borne fungal disease *Pachymetra chaunorhiza* and
6 increase soil pests, resulting in yield loss. *Pachymetra chaunorhiza* is unique to the
7 Australian sugar industry (Magarey et al., 2008). This study was undertaken as a
8 component of a project comparing reduced tillage with conventional land preparation to
9 determine the effect of reduced tillage and cultivar rotation on *Pachymetra chaunorhiza*
10 and the long-term yield of sugarcane. In addition advantage was taken of the different
11 tillage treatments to assess their impact on earthworm numbers as it was expected that
12 reduced tillage was likely to promote earthworm numbers.

13

14 **2. Materials and methods**

15 Field experiments were conducted at Feluga, near Tully (17°55'S, 140°54'E, mean
16 annual rainfall 4300 mm) and Bundaberg (24° 50'S, 153° 30'E, mean annual rainfall
17 1100mm) at sites where *Pachymetra chaunhoriza* (*Pachymetra* root rot) was known to be
18 prevalent. The soils at both sites are classified as yellow earths (Yellow Chromosol at
19 Tully and Yellow Kandosol at Bundaberg - Isbell, 1996) or Alfisols (Soil Survey Staff,
20 1990) or Luvisols (FAO-UNESCO, 1974). At both sites the experiments were established
21 on fields that had grown sugarcane for 10 – 15 years. The experiments were planted to
22 pachymetra susceptible and resistant cultivars of sugarcane over three years on 19 August
23 1996, 4 November 1997 and 21 June 1999 at Tully and 18 October 1996, 23 September

1 1997 and 23 September 1998 at Bundaberg. Plots at Tully were not planted in 1998 due
2 to very wet seasonal conditions. The experiments were continued until 2000, providing
3 from one to three years data after each planting date. In 2002 the second planted plots at
4 Tully (1997 planting) were re-planted on the same plots with the cultivars swapped to
5 assess the effect on *Pachymetra* inoculum of resistant cultivars planted on plots that
6 previously had grown a susceptible cultivar and vice versa. The 1997 planting had grown
7 a plant and two ratoon crops when this planting and cultivar swapping took place.
8 Replanting of the trial at Bundaberg and swapping the cultivars was not undertaken.
9 Plot size at Bundaberg was 7 rows by 15 m and at Tully 6 rows by 20 m. Row spacing
10 was 1.5 m, which was the existing spacing at both sites. The trials were a randomized-
11 block design with three replicates per treatment. The experimental detail and treatments
12 are provided in Braunack and McGarry (2006) and Table 1. The two sugarcane cultivars
13 grown at each site were Q115 and Q117 at Tully and Q138 and Q155 at Bundaberg. The
14 cultivars Q117 and Q138 are rated as resistant (rating 4 and 2, respectively) and Q115
15 and Q155 as susceptible (rating 6 and 9, respectively) to the soil-borne disease
16 *Pachymetra* root rot (Croft et al., 1998). These cultivars were selected to test
17 effectiveness of cultivar rotation on *Pachymetra* root rot, since the crop was planted
18 directly into the old row in treatments T2 to T4 (reduced tillage treatments) and as close
19 as possible to the old row in T1 (conventional tillage). Cultivars previously grown at
20 Tully were Q115 and Q117 while CP5121 and Q144 (rating 6 and 9, respectively for
21 *Pachymetra*) had been grown at Bundaberg.

22 *Pachymetra* spore counts were made prior to establishing the experiments and post-
23 harvest of the plant and each ratoon crop and after the cultivars were swapped on

1 replanting on bulked soil samples (0-45 cm depth). The technique of Magarey (1989) was
2 used for these counts. It involves the wet blending (kitchen blender) and sieving of soil
3 through a nest of sieves of different aperture (250, 125, 63, and 38 μ) followed by the
4 collection of the deposits on the 38 μ sieve. Soil deposits are then decolorized, the spores
5 stained blue and counted at 63x under a microscope. Spore identity is determined on
6 color of the stained spore, the appearance of the projections on the oogonial wall and
7 spore size. Counts are expressed in spores per kg (dry weight) soil. Samples for
8 *Pachymetra* assessment were collected within the row, near to the row and in the inter-
9 row. This allowed assessment of the distribution of *Pachymetra* with respect to tillage
10 treatment.

11 Earthworm counts were made on soil collected from five spade holes (0.2 x 0.2 x 0.2
12 m) per plot under one cultivar for each trial site, a modification of the Robertson et al.
13 (1994) technique. Samples were collected on 29 July 1997, 2 July 1998, 28 July 1999
14 and 4 July 2000 at Tully and on 27 July 1997, 22 April 1998, 24 August 1999 and 26
15 June 2000 at Bundaberg. Samples were placed on a white sheet and carefully hand sorted
16 to determine earthworm and earthworm egg numbers, which were counted as earthworms
17 while other fauna, were counted separately. Nematode counts were performed for the
18 Bundaberg site only, using the standard technique of Whitehead and Hemming (1965).
19 Samples for earthworm and nematode assessment were collected from within the row.

20

21 Shoot and stalk numbers were monitored in 10 m sections of the central two rows from
22 emergence to prior to harvest. Yield was determined at Tully by weighing stalks from the
23 four central rows of each plot harvested with a Toft 7000 mechanical harvester. At

1 Bundaberg 5 m lengths from the two central rows of each plot were weighed after being
2 cut at ground level by hand with a cane knife and leaves and tops removed. Plots were
3 harvested 12 months after planting. Commercial cane sugar (ccs, %) was measured on six
4 stalk sub-samples using the small mill technique (BSES 1984). CCS in conjunction with
5 cane yield was used to calculate sugar yield (tonnes sugar ha⁻¹) for each treatment.

6 Data were analysed by standard Analysis of Variance at the 5% significance level using
7 the Genstat13 statistical package (VSN International, 2010).

8 **3. Results**

9 Data are presented for the first (1996), second (1997) and third (1999) and the replant
10 (2002) at Tully; and for the first (1996), second (1997) and third (1998) Bundaberg
11 plantings to provide an indication of long-term response to tillage treatment. There were
12 few significant differences between treatments indicating that there are no adverse effects
13 of reduced tillage on cane and sugar yield.

14 The only time the soil was disturbed was at the initial planting of the experiment and re-
15 planting when the cultivars were swapped at Tully in 2002. There was no soil disturbance
16 during the crop cycle of first, second or third ratoon.

17 **3.1 Pachymetra status**

18 Results from both Tully and Bundaberg show that Pachymetra levels were significantly
19 lower under the resistant cultivars Q117 and Q138 compared with the susceptible
20 cultivars Q115 and Q155 (Table 2). Also there was a significant tillage by cultivar
21 interaction where spore numbers with the susceptible cultivar increased with less soil
22 disturbance. Further, there was a cultivar by crop class interaction, where spore numbers
23 with the susceptible cultivar built up the longer the crop was in the ground (Table 2).

1 Data for the distribution *Pachymetra* spores across rows and inter-rows indicated that the
2 number of *Pachymetra* spores decreased with distance from the cane row (Table 3).

3 When plots went back into Q117 after Q115, sampling at the end of the plant crop
4 showed that *Pachymetra* spore counts were significantly lower in the crop row, near the
5 row and in the inter-row compared with immediately prior to planting (Table 3) . There
6 was a significant cultivar by position by year interaction with significantly lower spore
7 numbers under the resistant cultivar, and further away from the crop row after the
8 cultivars were swapped (Table 3).

9 **3.2 Crop yield**

10 The yield of the susceptible cultivars (Q115, Q155) was significantly lower compared
11 with the resistant cultivars (Q117, Q138) for year one and year three planting at Tully and
12 all three plantings at Bundaberg (Table 4). It was only for the year two planting at Tully,
13 where seasonal conditions forced an 18 month fallow prior to planting that the resistant
14 cultivar did not out-yield the susceptible cultivar. Further, there was an interaction
15 between tillage treatment and cultivar for the year three planting at Tully and year one
16 planting at Bundaberg with yield of the susceptible cultivar decreasing with less soil
17 disturbance at both sites and the resistant cultivar increasing at Bundaberg (Table 4). This
18 effect carried through all ratoons at Bundaberg and coincides with an increase of
19 *Pachymetra* spores under the susceptible cultivar at both sites and only a small variation
20 in spores under the resistant cultivar. As the third planting at Tully was only grown for a
21 plant crop it is not possible to gauge whether this tillage effect would carry through to the
22 ratoons at Tully.

23 **3.2.1 Stalk development and yield after swapping cultivars (Tully)**

1 Mean stalk development was significantly superior under conventional cultivation on
2 day 99. However, differences became non-significant and relatively small as the season
3 progressed (Figure 1). The stool spray-out treatment (T3) seemed to lag behind the other
4 treatments for most of the sampling period; this was due largely to Q115 growing poorly
5 under the stool spray-out system (data not shown) consistent with its susceptibility to
6 *Pachymetra* root rot.

7 An early biomass sampling (60 days after planting) showed no significant effect of
8 tillage (T1:5.7, T2:6, T3:5.7 and T4:5.1 t/ha) or cultivar (Q115:5.3 and Q117:5.9 t/ha) on
9 biomass at this early stage. This confirms the results from the year one planting and
10 further indicates that crop yields were not compromised by reducing tillage for planting.

11 The final yield for the tillage treatments after swapping the cultivars is shown in Table 5.
12 There was no significant difference in yield (tonnes/ha) between tillage treatments.
13 However, there was a strong trend for cultivar differences ($p=0.065$) with Q117 out
14 yielding Q115, which has been consistent throughout the experiment and confirms the
15 *Pachymetra* rating for the two cultivars. Higher ccs with Q117 combined with the cane
16 yield trends resulted in significantly more sugar/ha with Q117 than for Q115.

17

18 **3.3 Earthworms**

19 In both experiments, earthworm numbers began to recover by the second ratoon with
20 greater numbers under reduced tillage than under conventional tillage (Figure 2, 3).

21 Numbers of earthworms at Tully were higher than those at Bundaberg which may be a
22 consequence of sampling time and/or associated with the variable nature of biological
23 populations (Figure 2, 3).

1

2 **3.4 Nematodes**

3 Counts for the two most prevalent nematodes in the Bundaberg experiment,
4 *Pratylenchus zae* and *Rotylenchus* are shown in Figure 4. There was no significant
5 difference in the numbers of *P. zae* between any of the tillage treatments, but there were
6 significantly greater numbers of *Rotylenchus* than *Pratylenchus* under all treatments
7 while T3 had significantly more *Rotylenchus* than the other tillage treatments (Figure 4).
8 There was no correlation between nematode numbers and *Pachymetra* spore counts (data
9 not shown).

10 **4. Discussion**

11 Previous studies on the soil borne fungal disease *Pachymetra chaunorhiza* have
12 concentrated on soil suppressiveness and resistant cultivars (Magarey et al. 2004) while
13 studies on nematodes have examined the effect of break crops/rotations on reducing
14 populations (Stirling et al. 2002). This is one of the first studies to examine the effect of
15 tillage on the known sugarcane soil borne fungal disease *Pachymetra chaunorhiza* when
16 planting back into the old crop row on crop response. In addition some preliminary
17 observations were made in relation to the effect of tillage on earthworms and nematodes
18 in sugarcane fields. These studies provide useful information for growers contemplating
19 adopting a controlled traffic, minimum tillage farming system.

20 **4.1 Pachymetra**

21 At both sites the resistant cultivars were effective in reducing the build-up of
22 *Pachymetra* throughout the duration of the crop cycle compared with susceptible

1 cultivars. Magarey and Mewing (1994) also found lower *Pachymetra* inoculum levels
2 under resistant cultivars.

3 The effect of tillage was less clear as *Pachymetra* spores are robust and not destroyed
4 by tillage *per se*... Tillage had a variable effect on *Pachymetra* spore numbers with fewer
5 spores under T1 (conventional cultivation) compared with the other treatments, which
6 may be due to a dilution effect associated with more soil disturbance compared with the
7 other tillage treatments. Further there was a trend for *Pachymetra* spore counts to be
8 greater under the stool spray-out treatment for the resistant cultivar at Tully. This may
9 reflect the minimal soil disturbance of the initial treatment resulting in less dilution and a
10 slower rate of decline as a result. Also there was an interaction between tillage and
11 cultivar and between cultivar and crop class. Spore numbers built up under the
12 susceptible cultivar and as the amount of soil disturbance decreased. However, under the
13 resistant cultivar spore numbers did not increase to the same extent, which agrees with
14 the results of Magarey and Mewing (1994). The variation in spore numbers with crop
15 class probably reflects seasonal conditions (Magarey and Mewing, 1994).

16

17 The planting in May 2002 where the tillage treatments were maintained but with the
18 cultivars being swapped provided information on management strategies. Basically, this
19 re-set the system and provided the opportunity to assess the effect of the previous tillage
20 treatments (levels of soil disturbance) and cultivar on crop performance with the cultivars
21 swapped. Such a strategy may provide a means to manage the levels and distribution of
22 *Pachymetra* spores in the soil. Croft and Saunders (1996) recorded higher numbers of
23 *Pachymetra* spores closer to the row than in the inter-row and on the basis of this

1 suggested that re-planting should be done in the old inter-row. However, this strategy
2 gives little consideration to the large amount of energy required to generate a seedbed in
3 the compacted inter-row area (Braunack et al., 1999). Reduced tillage for planting
4 sugarcane is being adopted by the industry to reduce the cost of planting and to
5 implement a controlled traffic farming system (Braunack et al. 2003, Braunack and
6 McGarry, 2006, Garside et al. 2004). Such a strategy is at odds with that proposed by
7 Croft and Saunders (1996) for Pachymetra management. Thus it is important that there is
8 no adverse effect of adopting a strategy that re-plants cane into the old row area from the
9 previous cycle. The results of these experiments indicate that such a strategy can be
10 developed by using Pachymetra resistant cultivars.

11 In the Tully experiment the resistant cultivar had the effect of moderating the spore
12 numbers that had built up under the susceptible cultivar. However, when plots were
13 planted with Q115 following Q117 there was a significant decrease in Pachymetra levels
14 in the row for T3 and T4 but not for T1 and T2 (Table 5). This result further indicates that
15 rotation of resistant and susceptible cultivars in conjunction with reduced tillage may be a
16 feasible strategy to manipulate Pachymetra levels to maintain yields in areas where high
17 Pachymetra spore counts may otherwise limit yield. However, long-term information
18 over a full-term second crop cycle is required to confirm the longevity or sustainability of
19 this strategy.

20 The number of Pachymetra spores that can result in economic loss is in the order of
21 forty thousand per kilogram of soil (Magarey et al., 2006). It can be seen from Table 5
22 that, after re-planting, levels of Pachymetra were lower than 40,000/kg, with the
23 exception of T2, T3 and T4 in the row (ex Q115),. Where levels are greater this

1 corresponds to the row position in plots that were previously under Q115. The reverse is
2 observed in the plots now under Q115 following re-planting since these plots were
3 previously under Q117 a resistant cultivar. By swapping the cultivars Pachymetra levels
4 remained below the threshold value of 40,000, however, it remains to be seen whether
5 this can be maintained for the crop cycle. The potential economic loss due to Pachymetra
6 has been estimated at \$914,000 for the Tully mill area (Magarey et al., 2006). This will
7 vary depending on soil type, environmental conditions and previous cropping history.
8 Cultivar rotation provides a strategy to minimise such losses within mill areas and to
9 manage Pachymetra disease levels in the soil. To derive the greatest benefit Magarey et
10 al. (2006) suggest that a regular soil sampling strategy be instigated to identify areas
11 where Pachymetra was above the threshold spore number. This would enable growers to
12 manage those areas by either planting resistant cultivars or growing a break crop.

13 The results here show that planting a resistant cultivar into the old row can reduce the
14 impact of Pachymetra on productivity. Such a strategy is suited to a controlled traffic
15 minimum tillage system as proposed by Braunack and McGarry (2006).

16 **4.2 Crop yield**

17 The response in crop yield was not consistent between the resistant and susceptible
18 cultivars at Tully while there was a more consistent response at Bundaberg. Also the
19 inter-action between tillage and cultivars was not consistent at both sites. This probably
20 reflects differences in seasonal conditions and the level of soil disturbance at planting
21 between the two sites. Crop yield differed significantly for the year one planting at Tully
22 and there was a non significant trend for the resistant cultivar to produce higher yields
23 with the year 2 planting and there was a significant difference in yield between cultivars

1 with the year 3 planting. There was a significant difference in yield for year one, two and
2 three plantings at Bundaberg. This is consistent with *Pachymetra* spore build-up under
3 susceptible cultivars with time under a sugarcane monoculture (Magarey et al., 2008).
4 However, it is not known how many spores of the total number are viable which may
5 influence the observed response.

6 The results presented here demonstrate that reducing the number of tillage operations
7 has not compromised yield, but the benefit of reduced cost in land preparation has been
8 gained (Braunack et al. 1999). The effect of swapping the cultivars may not be evident in
9 the plant crop since *Pachymetra* spore levels were generally below the economic
10 threshold under each cultivar at planting. However, differences may become more
11 evident with time as the crop cycle progresses and this should be monitored.

12 **4.3 Earthworms**

13 This is one of the few instances where the effect of different tillage strategies on
14 earthworm populations under sugarcane has been assessed. Earthworm numbers only
15 started to recover after the second ratoon crop and on the reduced tillage treatments
16 compared with the conventional treatment (Fig 2, 3). Similar results have been observed
17 under semi-arid (Wilson-Rummenic et al., 1999) and temperate (Douglas, 1987) cropping
18 systems. It has been shown that conventional tillage reduces the number of earthworms
19 and numbers had not recovered after one crop (Röhrig et al., 1998).

20 As earthworms are generally considered an indicator of soil health (vanVliet and
21 Hendrix, 2007), there is some indication that soil health has started to improve under the
22 reduced tillage system. Earthworms are also considered to be beneficial soil fauna
23 because they create pathways for water and air movement and for root growth.

1 Earthworms also incorporate organic materials and contribute to soil aggregate stability.
2 Studies have also shown that the presence of earthworms can substantially reduce the
3 fungal diseases of take-all and Rhizoctonia of wheat (Doube et al., 1994). It is thought
4 that the build-up of earthworms is a positive indicator that less soil disturbance may
5 enhance other beneficial soil organisms and microbiology. Although these experiments
6 only continued for a short period the number of earthworms increased under the reduced
7 tillage systems compared with the conventional system at both sites. However, this did
8 not consistently translate into significantly better yield. This needs to be monitored
9 further to confirm whether the trend continues and can be related to crop response over
10 time.

11

12 **4.4 Nematodes**

13 Nematode populations were assessed for the Bundaberg site only. It has been
14 demonstrated that nematodes can limit the productivity of sugarcane (Stirling et al.,
15 1996). The effect of tillage on nematode numbers under sugarcane in Australia is largely
16 unknown. The difference in populations of the two nematodes may be due to the fact that
17 different nematodes respond differently to tillage operations (Whalen and Sampedro,
18 2010). Also it is possible that an ineffective kill of the crop was not achieved by spraying;
19 enabling nematode numbers to build up on/in the surviving roots. Stirling (no date) has
20 shown that tillage initially reduces the population of nematodes and that recovery in
21 numbers occurs rapidly. It is speculated that the higher nematode (*Pratylenchus*)
22 population under T3 may be the result minimum soil disturbance in removing the old
23 cane stool and the opportunity time for the population to increase during the fallow

1 period. In contrast under T4 the old cane stool was removed with minimal soil
2 disturbance and there was no fallow period hence the population may not have been
3 reduced initially to the same extent. However, the differences observed may also be due
4 to the time of sampling (90 days after planting) and not reflect the effect of tillage
5 strategy. Similar observations were made under soybean comparing conventional and
6 reduced tillage strategies with greater nematode numbers in the row with zero and ridge
7 tillage compared with reduced or conventional tillage (Gavassoni et al. 2001). The
8 nematode counts tend to contrast with the *Pachymetra* counts, which were greater under
9 T4, but generally not significantly so from T3. A similar result was observed under semi-
10 arid conditions where greater nematode populations occurred in no-till soil compared
11 with conventionally tilled soil (Lopez-Fando and Bello, 1995). Seasonal and soil
12 conditions may be a greater influence on the build-up of soil-borne diseases and pests
13 over-and -above that of cultural operations. Soil tillage will have an immediate effect on
14 soil conditions which may favour one organism at the expense of others. This requires
15 further investigation.

16

17 **5. Conclusions**

18 There is no detrimental effect on cane yield by planting directly back into the old row
19 provided a *Pachymetra* resistant cultivar is used. Rotation of cultivars provides a means
20 to minimise the effect of *Pachymetra* root rot on productivity, along with the practice of
21 good crop hygiene of controlling volunteers.

22 Earthworms recovered more rapidly after minimal soil disturbance compared with
23 massive soil disturbance under conventional cultivation. This has implications for soil

1 health improvement and disease and insect control.

2 Reduced tillage needs to be considered as a viable alternative to conventional
3 cultivation for planting and to protect the soil resource of the sugar industry.

4

5 **6. Acknowledgments**

6 Funding was provided by SRDC and BSES. Neil Halpin, Luca Pippa, Peter Bakker,
7 Kelly Ritchie and Les Robertson provided field assistance. Gerry Borgna (Tully) and
8 Brian Harte (Bundaberg) are thanked for allowing trials on their properties.

- 1 Table 1 Sequence of tillage operations for each treatment at the Tully and Bundaberg
- 2 sites

Treatment	Tully	Bundaberg
Conventional (T1) (6-10 month fallow)	1 x rotary hoe (10 cm)	1 x rotary hoe (10 cm)
	4 x disc (20 cm)	2 x tine rip (40 cm)
	1 x rotary hoe (10 cm)	5 x disc (20 cm)
	Plant	1 x rotary hoe (10 cm)
		Plant
Stool ploughout (T2) (6-10 month fallow)	1 x rotary hoe skim (5cm)	1 x rotary hoe skim (5 cm)
	2 x tine (30 cm)	1 x tine (35 cm)
	Plant	4 x herbicide (8 l ha ⁻¹ glyphosate 180 g l ⁻¹ ai)
		1 x tine (30 cm)
		Plant
Stool sprayout (T3) (6-10 month fallow)	2 x herbicide (8 l ha ⁻¹ glyphosate 360 g l ⁻¹ ai)	3 x herbicide (8 l ha ⁻¹ glyphosate 360 g l ⁻¹ ai)
	1 x rotary hoe (5 cm)	Plant
	1 x tine (30 cm)	
	Plant	
Ploughout-replant (T4) (no fallow)	1 x rotary hoe skim (5 cm)	1 x rotary hoe skim (5 cm)
	2 x tine (30 cm)	2 x tine (30 cm)
	Plant	Plant

- 3
- 4 Numbers in parentheses are depths of tillage operations
