The future impact of ocean acidification (OA) on corals is disputed in part because mathematical models used to predict these impacts do not seem to capture, or offer a framework to adequately explain, the substantial variability in acidification effects observed in empirical studies. The build-up of a diffusive boundary layer (DBL), wherein solute transport is controlled by diffusion, can lead to pronounced differences between the bulk seawater pH, and the actual pH experienced by the organism, a factor rarely considered in mathematical modeling of ocean acidification effects on corals. In the present study, we developed a simple diffusion-reaction-uptake model that was experimentally parameterized based on direct microsensor measurements of coral tissue pH and O₂ within the DBL of a branching and a massive coral. The model accurately predicts tissue surface pH for different coral morphologies and under different flow velocities as a function of ambient pH. We show that, for all cases, tissue surface pH is elevated at lower flows, and thus thicker DBLs. The relative effects of OA on coral surface pH was controlled by flow and we show that under low flow velocities tissue surface pH under OA conditions (pH_{SWS} = 7.8) can be equal to the pH under normal conditions (pH_{SWS} = 8.2). We conclude that OA effects on corals in nature will be complex as the degree to which they are controlled by flow appears to be species specific.

Keywords: Climate change, carbonate chemistry, calcification, diffusive boundary layer

INTRODUCTION

Besides harboring a substantial proportion of the ocean's biodiversity, corals reefs are estimated to present an annual net global economic value of about \$30 billion. Coral reefs form when scleractinian corals (and a number of other calcifying reef organisms) can produce calcium carbonate (CaCO₃) skeletons faster than the sea can erode them (Cesar et al., 2003; Cohen and Holcomb, 2009) and these processes are inherently linked to the inorganic carbon chemistry of the oceans and atmosphere. Over the last half century, anthropogenic CO₂ emissions have caused atmospheric CO₂ to rise steadily from ~320 to ~390 ppm (IPCC, 2013). About 33% of this enhanced atmospheric CO₂ dissolves into the oceans, causing a shift in the seawater carbonate system that results in a decrease in both oceanic pH and the abundance of carbonate ions that corals use to build their skeletons. These effects of enhanced dissolution of CO₂ into the oceans are commonly termed

ocean acidification (OA) and have been identified as a global threat for coral reefs, predicted to slow coral calcification to a point where the rate of reef erosion exceeds the rate of skeletal accretion (Silverman et al., 2009; van Hooidonk et al., 2013). However, considerable controversy remains about the actual impact of ocean acidification on coral calcification (Pandolfi et al., 2011; Chan and Connolly, 2013).

The build-up of a diffusive boundary layer (DBL) surrounding aquatic organisms, wherein solute transport is controlled by diffusion (Jørgensen and Revsbech, 1985; Boudreau and Jørgensen, 2001), can lead to steep concentration gradients of metabolic gases and ions (Boudreau and Jørgensen, 2001). Such boundary layer effects can lead to pronounced differences between the bulk seawater pH, and the actual pH experienced by the organism, which is modulated by both mass transfer and metabolic activity (Kühl et al., 1995). Microsensor measurements within the DBL thus show elevated pH at the tissue surface of corals during daylight and lower pH in darkness as compared to the bulk seawater (Kühl et al., 1995; de Beer et al., 2000; Al-Horani et al., 2003). Hence, the actual tissue surface pH of corals does not necessarily correspond to values predicted in the bulk water phase by the end of the century, albeit current predictions are based upon such bulk water pH values (Hendriks et al., 2010). The lack of consideration of so-called boundary layer effects has been suggested as one factor leading to differences between early models predicting ocean acidification to be a major threat to marine biodiversity (Kleypas et al., 1999) and actual experimental evidence for the sensitivity of organisms to ocean acidification (Ries et al., 2009; Hendriks et al., 2010).

The tissue surface pH of coralline alga and foraminifera has been shown to be dependent on the metabolic rate of the organism (i.e., photosynthesis, respiration, and calcification) and the thickness of the DBL (Rink et al., 1998; Cornwall et al., 2013). In turn, DBL thickness is largely a function of fluid velocity and surface roughness (Jumars and Nowell, 1984; Denny, 1988). Moreover, metabolic rates are limited by different processes at different flow velocities. At high flows and thin DBLs, metabolic rates are most likely uptake-limited (i.e., limited by how quickly tissue can uptake solutes), whereas at low flows and thick DBLs, metabolic rates are likely to be diffusion-limited (i.e., limited by how quickly solutes can diffuse through the DBL). Although flow regime has a central role in determining coral surface pH, experimental studies on the effects of ocean acidification on coral calcification are just only beginning to recognize the interactive effects of ocean acidification and flow (Comeau et al., 2014). As such, previous studies have been carried out over a large range of flow velocities, ranging from 1 cm s^{-1} (Ohde and Hossain, 2004) to 20 cm s^{-1} (Langdon and Atkinson, 2005), making a direct comparison of ocean acidification-related effects difficult. Moreover, experiments have been carried out on a large variety of different species, and the effect of flow on respiration and photosynthesis has been shown to differ by genus (Hoogenboom and Connolly, 2009). Thus, flow velocity-driven differences in tissue surface pH could possibly explain some of the large variation in the response of corals to ocean acidification among experimental studies carried out so far.

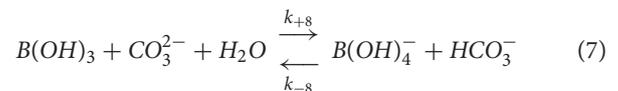

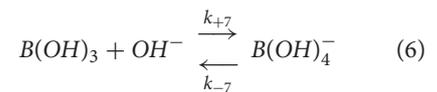

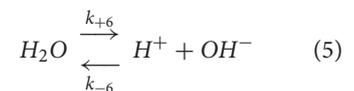

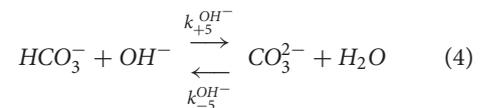

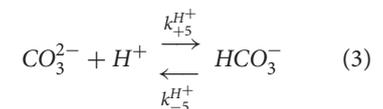

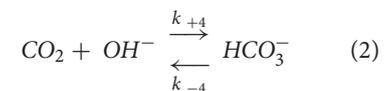

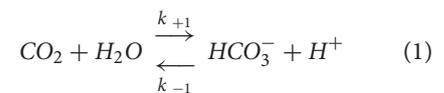

In this study, we investigated the drivers that determine tissue surface pH of corals. Specifically, we compared whether flow effects on tissue surface pH differed between massive and branching colonies when exposed to ambient and acidified conditions in the water column. To elucidate the factors determining tissue surface pH, we constructed a basic diffusion-reaction-uptake model that was experimentally parameterized based on direct microsensor measurements of coral tissue surface pH and O_2 . We evaluated how well the model predicted tissue surface pH in light, across a range of flows for two different coral species (*Favites* and *Pocillopora damicornis*), and under ambient vs. acidified conditions.

METHODS

The Model

We tested whether a simple diffusion-reaction-uptake model of the DBL, previously developed to describe the inorganic carbon chemistry in the DBL of foraminifera (Wolf-Gladrow et al., 1999), could replicate coral tissue surface pH as measured with microsensors. The model predicts concentration profiles of chemical species in the carbonate system from the coral surface to toward the bulk seawater as a function of distance from the coral surface (x), where x ranges from 0 at the coral surface to x_{bsw} at bulk seawater concentration. The model predicts the concentrations depending on diffusion, chemical conversion and the fluxes generated by metabolic rates.

The following chemical reactions are taken into account (from Zeebe and Wolf-Gladrow, 2001):

where k_{+i} and k_{-i} are the rate (kinetic) constants.

The basic equations of the model are of the following form

$$\frac{\partial c(x, t)}{\partial t} = \text{Diffusion} + \text{Reaction}$$

where $c(x, t)$ is the concentration of a particular chemical species at distance x from the coral surface, at time t . Specific sources and sinks are added for metabolic fluxes as boundary conditions at the coral surface.

Concentration profiles are predicted as a function of the distance from the tissue surface. The time needed to establish a steady state can be estimated by the diffusional time scale $\tau = l^2/D$, where $l \approx 100\text{--}2000 \mu\text{m}$ is the typical coral DBL thickness, and $D \approx 2 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ is the diffusion coefficient for CO_2 at 25°C and salinity of 35. Given these values, $\tau = 5\text{--}2000 \text{ s}$. The time scale for the slowest reaction, i.e., the conversion from HCO_3^- to CO_2 is in the order of 100 s (Wolf-Gladrow et al., 1999). Because the time scale for diffusion and reaction are small compared to typical time scales of photosynthesis, respiration and calcification in the natural environment (hours to days), a steady state of the fluxes will be assumed (as in Wolf-Gladrow et al., 1999). Thus

$$0 = \frac{\partial c(x, t)}{\partial t} = \text{Diffusion} + \text{Reaction}$$

The complete equations of the model are (Zeebe and Wolf-Gladrow, 2001):

$$0 = D_{\text{CO}_2} \frac{\partial^2 [\text{CO}_2]}{\partial x^2} + (k_{-1} [\text{H}^+] + k_{-4}) [\text{HCO}_3^-] - (k_{+1} + k_{+4} [\text{OH}^-]) [\text{CO}_2] \quad (8)$$

$$0 = D_{\text{HCO}_3^-} \frac{\partial^2 [\text{HCO}_3^-]}{\partial x^2} + (k_{+1} + k_{+4} [\text{OH}^-]) [\text{CO}_2] - (k_{-1} [\text{H}^+] + k_{-4}) [\text{HCO}_3^-] + (k_{+5}^{\text{H}^+} [\text{H}^+] + k_{-5}^{\text{OH}^-}) [\text{CO}_3^{2-}] - (k_{-5}^{\text{H}^+} + k_{+5}^{\text{OH}^-} [\text{OH}^-]) [\text{HCO}_3^-] + k_{+8} [\text{B}(\text{OH})_3] [\text{CO}_3^{2-}] - k_{-8} [\text{B}(\text{OH})_4^-] [\text{HCO}_3^-] \quad (9)$$

$$0 = D_{\text{CO}_3^{2-}} \frac{\partial^2 [\text{CO}_3^{2-}]}{\partial x^2} + (k_{+5}^{\text{H}^+} [\text{H}^+] + k_{-5}^{\text{OH}^-} [\text{OH}^-]) [\text{HCO}_3^-] - (k_{+5}^{\text{H}^+} [\text{H}^+] + k_{-5}^{\text{OH}^-}) [\text{CO}_3^{2-}] - k_{+8} [\text{B}(\text{OH})_3] [\text{CO}_3^{2-}] + k_{-8} [\text{B}(\text{OH})_4^-] [\text{HCO}_3^-] \quad (10)$$

$$0 = D_{\text{H}^+} \frac{\partial^2 [\text{H}^+]}{\partial x^2} + k_{+1} [\text{CO}_2] - k_{-1} [\text{H}^+] [\text{HCO}_3^-] + k_{-5}^{\text{H}^+} [\text{HCO}_3^-] - k_{+5}^{\text{H}^+} [\text{H}^+] [\text{CO}_3^{2-}] + k_{+6} - k_{-6} [\text{H}^+] [\text{OH}^-] \quad (11)$$

$$0 = D_{\text{OH}^-} \frac{\partial^2 [\text{OH}^-]}{\partial x^2} + k_{-4} [\text{HCO}_3^-] - k_{+4} [\text{OH}^-] [\text{CO}_2] - k_{+5}^{\text{OH}^-} [\text{OH}^-] [\text{HCO}_3^-] + k_{-5}^{\text{OH}^-} [\text{CO}_3^{2-}] + k_{+6} - k_{-6} [\text{H}^+] [\text{OH}^-] + k_{-7} [\text{B}(\text{OH})_4^-] - k_{+7} [\text{B}(\text{OH})_3] [\text{OH}^-] \quad (12)$$

$$0 = D_{\text{B}(\text{OH})_3} \frac{\partial^2 [\text{B}(\text{OH})_3]}{\partial x^2} + k_{-7} [\text{B}(\text{OH})_4^-] -$$

$$k_{+7} [\text{B}(\text{OH})_3] [\text{OH}^-] - k_{+8} [\text{B}(\text{OH})_3] [\text{CO}_3^{2-}] + k_{-8} [\text{B}(\text{OH})_4^-] [\text{HCO}_3^-] \quad (13)$$

$$0 = D_{\text{B}(\text{OH})_4^-} \frac{\partial^2 [\text{B}(\text{OH})_4^-]}{\partial x^2} - k_{-7} [\text{B}(\text{OH})_4^-] + k_{+7} [\text{B}(\text{OH})_3] [\text{OH}^-] + k_{+8} [\text{B}(\text{OH})_3] [\text{CO}_3^{2-}] - k_{-8} [\text{B}(\text{OH})_4^-] [\text{HCO}_3^-] \quad (14)$$

The model was used with two boundary conditions:

- 1) The concentration of chemical species at the upper boundary of the DBL are set as bulk seawater conditions (either ambient or acidified)
- 2) The flux of each chemical species through the tissue surface boundary is equal to the net metabolic rate that consumes or releases that species

In the model, the values of the rate parameters are fixed constants (Zeebe and Wolf-Gladrow, 2001). The model also has four variable input parameters—DBL thickness, net photosynthesis, net calcification and bulk seawater chemistry. To test the model, we measured DBL thickness, net photosynthesis and bulk seawater chemistry experimentally (details in following sections). Net calcification was assumed to be a fixed proportion of net photosynthesis as has been found in the literature (Schneider et al., 2009). Because the ratio of net calcification to net photosynthesis was found to remain constant across varying flows (Chan unpublished data), we assumed that the constant of proportionality between calcification and net photosynthesis was independent of flow. Conversely, previous studies have shown that the calcification to net photosynthesis ratio does decrease with ocean acidification (Chauvin et al., 2011), and suggested that different morphologies have different spatial patterns of zooxanthellae distribution and skeletal growth (Jokiel, 2011). Consequently, net calcification as a percentage of net photosynthesis was estimated separately for different colony morphologies and different bulk seawater conditions (see section Calculation of Ratio of Calcification to Photosynthesis below). With regards to DBL thickness, we used DBL thickness determined from O_2 profiles as a previous study has found no significant differences between DBL thickness when determined with O_2 or pH profiles (Cornwall et al., 2013).

Corals acquire HCO_3^- mainly from bulk seawater rather than from internal sources (Goiran et al., 1996; Schrammeyer et al., 2014). To keep electric charge neutrality, the uptake of HCO_3^- is compensated for by the uptake of an equal amount of H^+ . Thus the equations used to represent photosynthesis and calcification were:

The flux of HCO_3^- into the tissue is thus equal to net photosynthesis plus calcification while the flux of H^+ into the tissue equals net photosynthesis minus calcification.

Parameter Estimation and Model Validation

To parameterize the model, we required experimental estimates of DBL thickness and net photosynthesis at a number of flow

velocities and to evaluate the model, we required experimental estimates of tissue surface pH. We measured these. The experiments were conducted at the University of Technology, Sydney (UTS) using a massive *Favites* sp. and a branching *P. damicornis* colony (~3 cm diameter); the corals originated from the local coral holding facility at UTS (see Wangpraseurt et al., 2014 for details). Experiments were run in a custom-made black acrylic flow chamber (0.07 × 0.07 × 0.20 m). Microprofiles of O₂ within the DBL and tissue surface pH were measured under four flow velocities (0.1, 1, 2, and 5 cm s⁻¹). We did not investigate beyond flow velocities of 5 cm/s as DBL thickness asymptotically approaches zero as flow increases and effects of flow on coral metabolism have been found to be more pronounced at lower flows (Lesser et al., 1994; Hoogenboom and Connolly, 2009; Mass et al., 2010). Additionally higher flow speeds are difficult to generate in a small laminar flow chamber set up, where the higher speed can generate turbulence. For each flow velocity, corals were allowed to acclimate for 15–20 min (until tentacles were expanded again) before measurements began. Measurements were replicated at 4–6 points on a single colony from each species. Additional measurements were performed to evaluate whether the O₂ and pH dynamics are simultaneous. O₂ concentration [hereafter (O₂)] and pH at the tissue surface was recorded simultaneously as flow velocity was varied in light and darkness. The measurements were thus only performed to evaluate dynamic differences in the behavior of the two parameters and we did not wait until the system was in entire steady state. Measurements were carried out at a temperature of 25.8°C and a salinity of 33.4, which are the prevailing conditions in the coral holding tanks. Microsensor measurements were performed at the branch tips for branching species and on the coenosarc, i.e., the tissue connecting two polyps, for massive species as these regions of the coral have been shown to have the highest calcification rate for each morphology, respectively (de Beer et al., 2000; Jokiel, 2011). Seawater was obtained from a long-term acidification experiment being run at UTS.

To evaluate how well the model captured DBL dynamics under ocean acidification, we carried out additional measurements on the same *Favites* sp. colony. The colony was placed in acidified seawater (pH_{SWS} = 7.8 (±0.08 SD; *n* = 10) representative for predicted conditions in the year 2100 under RCP 6.0, and TA = 2325 μmol kg⁻¹ (IPCC, 2013) and allowed to acclimate for 30 mins (until tentacles were expanded again) before measurements began. The O₂ and pH profiles within the DBL were measured under the same flow velocities as used in the experiments with normal seawater (see above). Measurements were replicated at 2 points. Acidified seawater was obtained by sparging CO₂ gas into tanks controlled via a pH controlling system (7070/2 pH controller set Tunze Aquarientechnik GmbH, Penzberg, DE), allowing for fine automated control of pH_{SWS} (within ± 0.01 pH_{SWS} units) for the duration of the experiment. The pH electrodes of the pH controlling system were calibrated every week using pH_{SWS} 5 and 7 standard buffers (Fluka, Sigma-Aldrich, CH). Bulk seawater pH of the flume was monitored continuously and the water replaced constantly to limit the pH increase (due to equilibrium with air) to 0.05 units.

Measurement of CO₂ System Parameters in Bulk Seawater

pH was measured using a Conductivity/TDS-pH meter (WP-81 TPS, Germany) calibrated with standard 4 and 7 buffers (TPS, Germany). Total alkalinity (TA) was measured by titrating 30 g water samples with 0.1 molL⁻¹ hydrochloric acid with an autotitrator (T50 Titrator Mettler Toledo, United States; as in Sinutok et al., 2011). TA was determined from the average of three independent water samples.

Microsensor Measurements

Microscale O₂ concentration measurements were done with Clark-type O₂ microsensors connected to a pA-meter (PA2000, Unisense A/S, Aarhus, Denmark). The O₂ microsensors (OX25, Unisense, Denmark) have excellent temporal and spatial resolution and are further characterized by excellent signal stability. The tip diameter of the O₂ sensors was 25 μm and the sensors had a 90% response time of <0.5 s. The O₂ sensors were linearly calibrated using standard procedures (see Wangpraseurt et al., 2012). A two-point calibration was performed from signal readings in air saturated water and anoxic water (flushed with N₂). The measurement signal in steady-state was highly reproducible as the signal drift was <1% (stirring sensitivity <1%). The O₂ sensors provided accurate measurements with a detection limit of 0.3 μM (<http://www.unisense.com>). The percent air saturation in seawater at experimental temperature and salinity was transformed to O₂ concentration (μmol O₂ L⁻¹) using gas tables (Ramsing and Grundersen, Unisense, Denmark, <http://www.unisense.com/files/PDF/Diverse/Seawater%20&%20Gases%20table.pdf>).

Tissue surface pH was measured with pH glass microelectrodes with an outer tip size of 40–60 μm (pH-50 Unisense A/S, Aarhus, Denmark). The microelectrodes were connected to a high impedance mV meter (pH/mV-Meter Unisense A/S, Aarhus, Denmark) measuring the pH-dependent microelectrode potential against a standard calomel reference electrode immersed in the same medium as the microelectrode. The pH microelectrodes were calibrated in standard pH buffers (pH 4, 7, and 10; TPS, Germany) as described previously (Kühl et al., 2012). The sensors exhibited a near-ideal Nernstian response of around 55 mV per pH unit change. The sensor signal was very stable (<1% deviation) and the pH microsensor provided accurate measurements with a detection limit of 0.1 pH units and a 90% response time of <10 s (<http://www.unisense.com>). The difference between bulk seawater pH measured using pH microelectrodes and pH electrodes of the pH controlling system (mentioned in section Parameter Estimation and Model Validation above) was used to calculate the offset to convert pH from NBS scale to SWS scale.

Visible light was provided by a tungsten-halogen lamp of constant color temperature (KL2500 Schott AG, Mainz, Germany). The downwelling photon irradiance (PAR, 400–700 nm) was measured with a calibrated spherical quantum sensor (US-SQS/L, Heinz Walz GmbH) connected to a light meter (LI-250A, Li-COR). All measurements were carried out under a downwelling irradiance of 800 μmol photons m⁻² s⁻¹.

For profiling, the microsensors were mounted on PC-controlled motorized micromanipulators for automatic profiling (MU1 Pyro-Science GmbH, Germany). The micromanipulators were fixed on a heavy-duty vibration-free metal stand. Positioning of the microsensors was facilitated by the manufacturer's software (Profix, Pyro-Science GmbH, Germany).

Measurements were done with the O₂ microelectrode mounted vertically, while the pH microelectrode was mounted at a 45° angle and the light at a 25° angle relative to vertical. Microsensor measurements were done in vertical steps of 25–100 μm. Determination of the tissue surface position was done by observation of the microsensor tip under a dissection microscope while slowly approaching it to the coral surface. In the following, all depths are given relative to the coral tissue surface (depth = 0 μm), where negative depths indicate distance above the tissue surface.

DBL Thickness Calculation

The effective DBL thickness was determined from the intercept between the linear extrapolation of the O₂ concentration profile at the coral surface and the bulk seawater concentration (Jørgensen and Revsbech, 1985). The slope of the O₂ concentration vs. distance data was fitted using the linear model function (lm) in R (R Core Team, 2013).

Net Photosynthesis Calculation

The diffusive fluxes of O₂, $J(x)$ were determined from steady state O₂ concentration profiles by Fick's first law of diffusion:

$$J(x) = -D_0 \frac{\delta C(x)}{\delta x} \quad (15)$$

where is $\delta C/\delta x$ the slope of the O₂ profile at depth x , and D_0 is the molecular diffusion coefficient of O₂ in water corrected for temperature ($2.1707 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$), as taken from tabulated values provided by Unisense (Ramsing and Gundersen).

Calculation of Ratio of Calcification to Photosynthesis

The model and data from one flow (5 cm s^{-1}) were used to fit the ratio of net calcification to net photosynthesis. Ratio of net calcification to net photosynthesis was independently fitted for each species and acidified condition. We then tested model predictions against the other three flows (0.1 , 1 , and 2 cm s^{-1}). We also tested a model where the ratio of net calcification to net photosynthesis was constrained to be equal across species and acidified condition.

Statistical Analysis

To determine whether there was statistical support for calibrating the model differently for different colony morphologies or bulk seawater conditions, ANCOVA was used to test whether species interacted with flow in determining DBL thickness, photosynthesis and tissue surface pH, and to test whether species/bulk seawater pH interacted with flow in determining tissue surface pH. ANCOVAs were carried out using the `aov()` function in R.

RESULTS

Parameter Estimation

DBL Thickness and Net Photosynthesis

The DBL thickness exhibited a negative power law relationship with flow for both *Favites* and *P. damicornis*, i.e., it was thick at low flow and thinned out as flow increased (Figure 1A, see Figure S1 in Data Sheet 1 for examples of O₂ microprofiles, see Datasheet 2 for raw O₂ microsensor data: depth from tissue surface against percentage air saturation). Likewise, DBL thickness for *Favites* in acidified seawater also exhibited a negative power law relationship, however the slope was shallower. The largest change in DBL thickness occurred between 0 and 2 cm s^{-1} (Figure 1A). For any given flow velocity, *Favites* had a thicker DBL than *P. damicornis*. Flow and species interacted significantly to affect net photosynthesis, with net photosynthesis increasing more with increasing flow for *Favites* than for *P. damicornis* (Figure 1B; Table 1). Flow and bulk seawater pH did not interact significantly to affect net photosynthesis, nor did bulk seawater pH have any effect on net photosynthesis (Table 2).

Microsensor Measurement of Tissue Surface pH

Elevation of tissue surface pH was plotted against flow for various species and acidified conditions (Figure 2A) because we are comparing two different bulk seawater scenarios (ambient pH_{SWs} bulk = 8.2 and acidified pH_{SWs} bulk = 7.8). Using elevation of tissue surface pH allowed us to highlight that tissue surface pH was elevated more under acidified conditions than it was under ambient conditions. Flow significantly affected tissue surface pH with lower flows leading to increased elevation in tissue surface pH (Figure 2A; Table 3). Species also had a significant effect on surface pH, with *Favites* showing a larger increase in tissue surface pH (0.4–0.6 pH units) than *P. damicornis* (0–0.3 pH units; Table 3). There was no interaction between flow and species in determining tissue surface pH. For *Favites*, the highest deviations from bulk seawater pH occurred

under flows of 1 and 2 cm s^{-1} , but even at a flow of 0.1 and 5 cm s^{-1} tissue surface pH was still significantly elevated (**Figure 2A**). For *P. damicornis*, tissue surface pH was highest at close to stagnant conditions. Enhanced flow velocities increased tissue surface pH up until a velocity of $\sim 5 \text{ cm s}^{-1}$. Tissue surface pH did not differ from the bulk seawater pH at flow velocities $> 5 \text{ cm s}^{-1}$ (**Figure 2A**).

There was a significant effect of bulk seawater pH on elevation of tissue surface pH (**Table 4**). The tissue surface pH of *Favites* showed a larger elevation under acidified conditions (bulk seawater pH_{SWS} of 7.8) than under ambient pH conditions (bulk seawater pH_{SWS} of 8.2), at flows of 1 and 2 cm s^{-1} (**Figure 2A**), so much so that at flow velocity of 2 cm s^{-1} , there was no difference in tissue surface pH under ambient and acidified conditions (i.e., pH value of 7.8 in bulk seawater + 0.8 elevation = tissue surface pH of 8.6 under acidification, vs. pH value of 8.2 in bulk seawater + 0.45 elevation = tissue surface pH of 8.65 in ambient conditions).

Model Predictions

Net calcification was estimated to be 65, 55, and 80% of net photosynthesis in *Favites*, *Favites* under acidified conditions, and *P. damicornis*, respectively. Using these calcification rates, the diffusion-reaction-uptake model predicted tissue surface pH quite well for both *Favites* and *P. damicornis*, under ambient

TABLE 4 | ANOVA summary for effects of flow and bulk seawater pH on tissue surface pH of *Favites*.

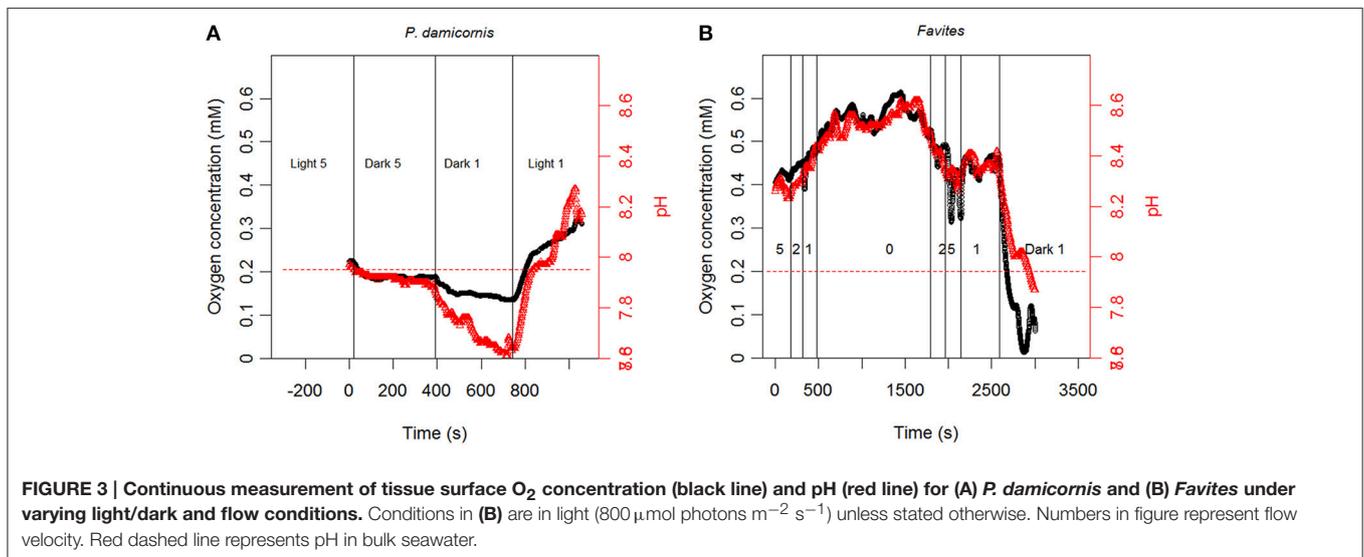

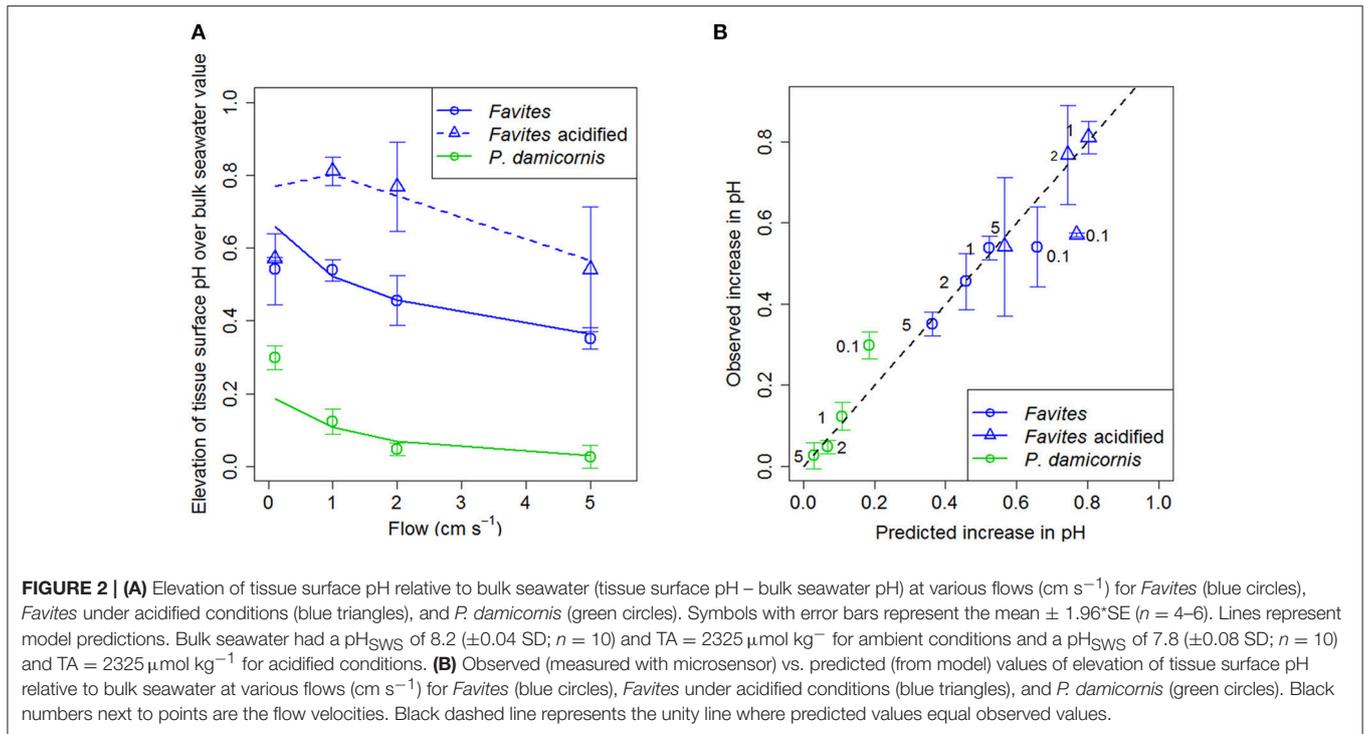

Factor	<i>F</i>	<i>df</i>	<i>p</i>
Flow	12.32	1	0.002
Bulk seawater pH	25.37	1	<0.001

Bold values represent significant effects.

and acidified conditions, at all flow velocities except for 0.1 cm s^{-1} (**Figures 2A,B**). At a flow velocity of 0.1 cm s^{-1} , the model predicted a higher tissue surface pH for *Favites* and a lower tissue surface pH for *P. damicornis* than those observed (**Figure 2A**). Overall, however, the R^2 for a linear regression of observed vs. predicted values was 0.9229 (**Figure 2B**). Moreover, the slope (0.881) and intercept (0.035) of the linear regression were not significantly different from the slope (1) and intercept (0) of the unity line (where observed values equalled predicted values) ($\chi^2 = 3.0811$, $p = 0.2143$). Thus, the model showed both high precision and low bias as a predictor of the coral tissue surface pH. When the ratio of net calcification to net photosynthesis was assumed to be constant (65%) across all species and treatments, the model fit was almost as good, and the slope and intercept for the linear regression of observed vs. predicted values were still not significantly different from those of the unity line (Figure S2 in Data Sheet 1).

Correlation between Net Photosynthesis and Tissue Surface pH

Our measurements showed that (O_2) and pH measurements dynamics occurred simultaneously (**Figure 3**). Changes in (O_2) and pH were positively correlated across flow velocities and illumination conditions (light or darkness), with illumination leading to elevation in both (O_2) and pH (relative to the

bulk seawater) and darkness leading to reductions (**Figure 3**). The magnitude of elevation/reduction was flow dependent with larger elevation/reduction under lower flows and smaller elevation/reduction at higher flows (**Figure 3**).

DISCUSSION

For benthic macroalgae, it is known that a thickening of the DBL, via reduced flow velocity, causes an elevation of tissue surface pH which reduces the negative effects of ocean acidification (Cornwall et al., 2013, 2014). In corals, it has only recently been

shown that water flow modulates the response of coral reef communities to ocean acidification, even though the DBL has long been known to elevate tissue surface pH (Kühl et al., 1995; de Beer et al., 2000; Al-Horani et al., 2003; Comeau et al., 2014). In this study, we found that lower flow and thus thicker DBLs lead to increases in the elevation of tissue surface pH. Moreover, under ocean acidification, elevations in tissue surface pH reached the point where tissue surface pH was similar under ambient and acidified conditions. We also showed that the degree of elevation of tissue surface pH differed with species, where *Favites* exhibited higher tissue surface pH elevation as compared to *P. damicornis*.

Generally, the DBL is a function of the local hydrodynamic conditions. These in turn are controlled by surface roughness and microtopography and the ambient flow velocity. The insertion of the microsensors in the water above a solid structure can lead to a local acceleration of flow leading to a compression of the DBL (Glud et al., 1994), but a new steady state is typically established very quickly and local fluxes adjust to the somewhat thinner DBL accordingly (Lorenzen et al., 1995). Using microsensors, we verified that DBL thickness decreases exponentially with increasing flow for both *Favites* and *P. damicornis* under ambient conditions. For *Favites* under acidification, while we find that higher flow still leads to thinner DBLs, the relationship is less well defined. This effect likely reflects behavioral change of the coral tissue under acidification. Coral tissues can contract and expand and change their surface structure depending on environmental conditions, which can then affect the thickness of the DBL.

The diffusion-reaction-uptake model developed for foraminifera was able to predict the tissue surface pH of *Favites* and *P. damicornis*, in light, under ambient and acidified conditions across a range of flows. This suggests that tissue surface pH is driven by diffusion-reaction-uptake kinetics alone and that the two model input parameters (DBL thickness and the difference in coral metabolic rates) are the key factors determining pH at the tissue surface. Thicker DBLs and larger differences in coral metabolic rates lead to larger elevation of tissue surface pH. In line with previous work, we found that photosynthesis increased with flow, with the increase dependent on species (Lesser et al., 1994; Hoogenboom and Connolly, 2009). Moreover, microsensor profiles showed that the dynamics of tissue surface O₂ concentration and pH were tightly linked across a range of flows, demonstrating correlation between photosynthesis and elevation of tissue surface pH. Also, the model fits suggest that the ratio of calcification to photosynthesis (g_n/p_n) is independent of flow. As flow and thus photosynthesis decrease, the constant ratio means that the difference between photosynthesis and calcification rate decreases and so does the elevation of tissue surface pH. However, we found that elevation in tissue surface pH was largest under low flow. Moreover, sensitivity analysis shows that the model is not sensitive to g_n/p_n [Figure S2 in Data Sheet 1; the similarity of **Figure 2B** (ratio allowed to vary) and Figure S2 (ratio constrained to be 0.65) illustrates how insensitive the model is to changes in ratio of calcification to photosynthesis]. Thus we are able to conclude that DBL thickness is the major mechanism through which flow influences tissue surface pH. Our results are consistent with the hypothesis that morphology leads to differences in DBL thickness i.e., the DBL of massive species are thicker than those of branching species, despite similar regimes of ambient flow (Jimenez et al., 2011). However, our study species differed in other ways, such as surface roughness (due to corallite size), metabolic rates, tissue thickness and roughness, and zooxanthellae distribution which could also be the driving factors behind this variation. Thus we cannot, at this stage, unambiguously attribute the differences observed to colony morphology: more corals will need to be studied to determine fully the relative importance of these different species traits in driving the differences observed here.

Under ocean acidification conditions, we found that net photosynthesis did not increase, which is consistent with previous work (Reynaud et al., 2003; Schneider and Erez, 2006; Anthony et al., 2008; Marubini et al., 2008; Houlbreque et al., 2012; Agostini et al., 2013). We did however find that, under acidification, *Favites* had a thinner DBL (compared to ambient treatment) at lower flows and a thicker DBL at higher flows. Moreover, constraining the ratio of calcification to photosynthesis to be the same across treatments did not affect model fit. These observations suggest that the increase in tissue surface pH of *Favites* under ocean acidification was due to an increase in DBL thickness. This is likely due to behavioral change of the coral tissue under acidification. However, why this occurs, and the extent to which it occurs in other species, is a topic for future research.

The tissue surface pH prediction from the diffusion-reaction-uptake model differed most from the dataset at flows of 0.1 cm s⁻¹ (close to stagnant), over-predicting it for *Favites* and under-predicting it for *P. damicornis*. A recent study has shown that, under conditions of zero flow, corals have the ability to use cilia beating to vigorously stir the water at the coral surface, leading to decreased DBLs and increased mass transfer (Shapiro et al., 2014). Under stagnant conditions, this biologically driven mass transport, rather than molecular diffusion, was shown to affect the exchange of nutrients and O₂ between the coral surface and the environment (Shapiro et al., 2014). However, for higher flow velocities, tissue surface pH was well predicted by molecular diffusion, thus suggesting that while diffusion is the prime transport mechanism for corals under low and moderate flow velocities, mass transfer may be driven by other processes (e.g., cilia beating) at near stagnant conditions.

Oceanic pH is predicted to decline by 0.3–0.4 pH units by the end of this century (Caldeira and Wickett, 2003). Attempts to experimentally determine the effect this decline in pH will have on coral calcification have found obtained widely varying results, from increases to decreases (Hendriks et al., 2010; Chan and Connolly, 2013; Kroeker et al., 2013). While recent studies have suggested that species specific differences in the capacity of corals to upregulate pH within the calcicoblastic layer may be the underlying reason for this large variability in experimental results (McCulloch et al., 2012), our results suggest that differences in species specific boundary layer dynamics, and thus tissue surface pH, also contribute to the variability. The predicted decline in pH due to ocean acidification is well within the range of tissue surface pH elevations measured for massive species (0.2–0.6), but higher than that of branching species (0–0.2; **Figure 2A**). We found that at flow velocities of 2 cm s⁻¹, tissue surface pH of *Favites* was elevated to similar absolute values under ambient and acidified treatments, regardless of bulk seawater pH. That is, under acidification, tissue surface pH was elevated above bulk seawater pH by a larger amount than it was under ambient pH. This finding is consistent with that of Agostini et al. (2013) showing that tissue surface pH values of *Galaxea fascicularis* were not significantly different in seawater equilibrated with atmospheric CO₂ levels of 400 and 700 ppm under a flow of 5 cm s⁻¹. This elevation in pH leads to a net increase in aragonite saturation state (a measure of the thermodynamic

potential for aragonite, the specific mineral form of calcium carbonate from which coral skeleton is constructed, to precipitate or dissolve) at the tissue surface, especially under acidified conditions, where aragonite saturation state at the tissue surface is double aragonite saturation state in bulk seawater [Figure 4; aragonite saturation state calculated from model projections of tissue surface pH and DIC with the program Seacarb (Lavigne and Gattuso, 2011) in R (R Core Team, 2013)]. However, it is important to bear in mind that corals with more elevated tissue surface pH in light also have more depressed tissue surface pH in darkness. It has been suggested that corals living in environments that frequently experience extreme temperatures may be more resistant to bleaching compared to more stable environments (Jokiel and Coles, 1990; Marshall and Baird, 2000), and we hypothesize that the same may apply to corals—that some corals may be more resistant to ocean acidification because they frequently experience larger pH fluctuations. Consistent with this hypothesis, diurnally oscillating pH has been shown to enhance coral recruit growth as compared to consistent ambient or acidified treatments (Dufault et al., 2012). While increase elevation and reduction in tissue surface pH on a diurnal time scale may enhance resistance to ocean acidification, there is a need to consider the overall effect of thicker DBLs on coral growth as thicker DBLs also hinder nutrient uptake by corals from surrounding seawater and also result in elevated temperatures in the DBL (Jimenez et al., 2011). Lastly, although these elevations in tissue surface pH have been found at relatively low flows compared to that which is typically found on reefs, ranging from 6–35 cm s⁻¹ (Sebens et al., 1997; Fulton and Bellwood, 2005), periods of such low flow (<5 cm s⁻¹) are not uncommon for shallow reef flats (e.g., Helmuth et al., 1997) or lagoonal habitats under calm weather conditions (e.g., Smith and Birkeland, 2007).

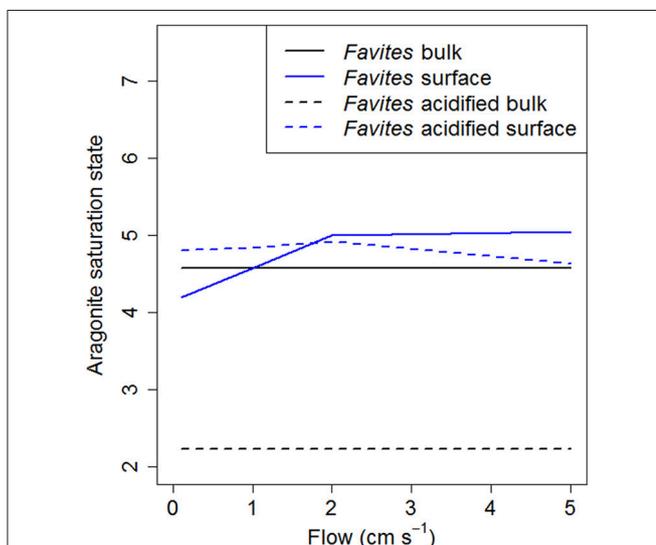

FIGURE 4 | Model predictions of aragonite saturation state at various flows for *Favites* under ambient (solid lines) and acidified (dashed lines) conditions. Aragonite saturation state of bulk seawater is shown in black and at the tissue surface shown in blue.

Our results also highlight several potentially fruitful areas of future research. Firstly, we have not tested our model against measurements in darkness. As stated above, situations with more elevated tissue surface pH in light will also have more depressed tissue surface pH in darkness, and it is the net effect on tissue surface pH over a 24-h period which will affect coral metabolism. Secondly, we do not know the extent to which the differences in ambient vs. acidification found in this study for *Favites* are also prevalent in other species. Lastly, our study focused on the effects of unidirectional flow, however oscillatory flow resulting from the propagation and transformation of surface gravity waves can dominate the flow environments of many shallow reef communities. Compared to unidirectional flow of the same velocity, oscillatory flow has been shown to increase the penetration of flow into branching corals, reduce boundary layer thickness, and increase mass transfer to and from the coral (Falter et al., 2005; Reidenbach et al., 2006). Thus, an oscillatory flow with a given magnitude may produce effects comparable to much larger magnitude unidirectional flows.

Our study shows that a basic diffusion-reaction-uptake model is able to predict well tissue surface pH. This suggests that tissue surface pH is driven by boundary layer thickness. Our findings suggest that, due to thicker DBLs some species can have higher elevation (in light) and larger depression (in darkness) of tissue surface pH than others, especially under ocean acidification. However, these elevations in tissue surface pH are strongly flow dependent, most pronounced under low flows, and also species specific. The buffering of ocean acidification effects for some corals, through the establishment of the DBL, will depend on the local flow microenvironment experienced on the reef. We conclude that OA effects on corals in nature will be complex as the degree to which they are controlled by flow appears to be species specific.

AUTHOR CONTRIBUTIONS

Conceived and designed the experiments: NC. Performed the experiments: NC and DW. Analyzed the data: NC and DW. Contributed reagents/materials/analysis tools: NC, MK, and SC. Wrote the paper: NC, DW, MK, and SC.

ACKNOWLEDGMENTS

We are grateful to Katherina Petrou for assistance with chemical analysis, and to the four anonymous reviewers and subject editor for providing comments and suggestions that improved the manuscript. Financial support for this project was provided by the Australian Research Council, James Cook University, Danish Council for Independent Research/Natural Sciences, The Plant Functional Biology and Climate Change Cluster, and the University of Technology, Sydney.
