Introduction
The Tibetan Plateau includes two important metallogenic belts, the Gangdese metallogenic zone in southern Tibet and the newly delimited Bangong-Nujiang metallogenic belt in central Tibet (Geng et al., 2016). The Bangong-Nujiang metallogenic belt is considered to be a Fe-Cu-Au metallogenic belt since the discovery of the Tielongnan giant porphyry-epithermal Cu-Au deposit (Tang et al., 2014), the Duobuza large porphyry deposit (Li et al., 2012) and the Ga'erqiong-Galale large skarn Cu-Au deposit (Zhang et al., 2015). The Jiaoxi quartz vein-type tungsten deposit (WO³) 39,000 t, Wang et al., 2018) is the first quartz-vein type tungsten deposit found in this belt.

Geological features
The Jiaoxi deposit is located in the Shiquanhe-Nam Tso Mélange Zone. The strata exposed in the district includes the Early Cretaceous Shiquanhe ophiolite mélangé of sandstone, shale and sheet of ophiolite. Sandstones and shales in the deposit area have been locally metamorphosed, due to the emplacement of the granites in this area. Intrusions in the deposit includes biotite monzogranite porphyry, granite porphyry and monzogranites in this area. Intrusions in the deposit include biotite monzogranite porphyry, granite porphyry and muscovite monzogranite. Muscovite monzogranite has only been found in drill core at a depth of 402 to 415 m. Tungsten-bearing quartz vein is the main mineralization type in this deposit. The extensional veins are subvertical and strike approximately north-south. Wolframite and scheelite coexist with chalcopyrite, pyrite, molybdenite, galena, sphalerite, quartz, beryl, lepidomelane, fluorite, ankerite and topaz (Fig. 1a). So far, around 70 tungsten orebodies have been discovered at surface. The orebodies are mainly hosted in the sandstone and shales (Fig. 1b, c, d). However, drill core inspection revealed that the biotite monzogranite porphyry and the muscovite monzogranite also host some orebodies (Fig. 1g, h).

Three stages of mineralization have been identified. The first, prominent, oxide stage is characterized by the development of the following vein types:

- rare quartz + molybdenite ± feldspar (in the biotite monzogranite only) veins (Fig. 2f);
- quartz + wolframite + lepidomelane veins (Fig. 2h);
- quartz + wolframite veins (Fig. 2c);
- quartz + wolframite + fluorite veins (Fig. 1b);
- quartz + pyrite + wolframite + lepidomelane veins (Fig. 1d), and
- quartz + lepidomelane + beryl + topaz veins.

The second sulfide stage is characterized by different types of sulfide-bearing veins, including:

- quartz + pyrite + chalcopyrite + galena + sphalerite veins (Fig. 2i), and
- quartz + pyrrhotite + chalcopyrite veins and the quartz + lepidomelane + pyrite + chalcopyrite veins.

The final fluorite-carbonate stage is characterized by pure fluorite veins, pure ankerite veins, fluorite + lepidomelane veins, quartz + pyrite veins, lepidomelane + scheelite veins and minor quartz + calcite veins.

W-Nb-Ta mineralization potential
The discovery of Ta-Nb oxides-containing pegmatite in the northeast of Jiaoxi deposit (Fig. 3a, b), indicates the potential for W-Nb-Ta mineralization in this district. Field data indicate that this pegmatite is exposed at a large scale in this district.
